Abstract—This work presents an extension of Karatsuba’s method to efficiently use rectangular multipliers as a base for larger multipliers. The rectangular multipliers that motivate this work are the embedded 18×25-bit signed multipliers found in the DSP blocks of recent Xilinx FPGAs: The traditional Karatsuba approach must under-use them as square 18×18 ones. This work shows that rectangular multipliers can be efficiently exploited in a modified Karatsuba method if their input word sizes have a large greatest common divider. In the Xilinx FPGA case, this can be obtained by using the embedded multipliers as 16×24 unsigned and as 17×25 signed ones. The obtained architectures are implemented with due detail to architectural features such as the pre-adders and post-adders available in Xilinx DSP blocks. They are synthesized and compared with traditional Karatsuba, but also with (non-Karatsuba) state-of-the-art tiling techniques that make use of the full rectangular multipliers. The proposed technique improves resource consumption and performance for multipliers of numbers larger than 64 bits.

I. INTRODUCTION

Karatsuba’s method [1] was the first method for computing products with sub-quadratic complexity. It trades multiplications for additions, which are cheaper. It will be exposed in detail in Section II. In its original formulation, Karatsuba’s algorithm is only expressed in terms of square multipliers, i.e., multipliers whose two inputs have the same number of digits. However, the multiplier resources available in recent Xilinx FPGAs are not square: they typically consist of a 18×25-bit signed multiplier which can be used for 17×24-bit unsigned multiplication [2]. The Karatsuba method is therefore inefficient on such FPGAs [3], [4]: to apply it, one either needs to under-use the DSP blocks (use them as 17×17-bit multipliers), or complement them with (slower) logic to turn them into 24×24-bit multipliers. The first option is preferred, as it can exploit the optional pre-adder and post-adder/accumulator that surround the multiplier in a DSP block [3], [4].

This article attempts to reconcile Karatsuba’s method with FPGA hardware whose DSP blocks are rectangular. It first slightly generalizes the classical Karatsuba formulation. It then shows how rectangular multipliers can be used under certain constraints on their aspect ratio.

This problem corresponds to sparse polynomial multiplication, so the suggested algorithms also find use here. Previous work in this area primarily focus on asymptotically efficient results or comparisons for polynomials with a random sparseness [5], [6]. In [6], the authors mention regarding Karatsuba’s method for sparse polynomial multiplication: “In the sparse case this phenomenon hardly occurs, and it is commonly admitted that this approach is useless”. The current work shows that there are use cases, at least when the sparseness is regular, and that significant savings can be obtained compared to a straightforward evaluation. The authors are not aware of any explicit results for multiplication of sparse polynomials with a regular sparseness.

Back to FPGAs, the proposed technique is able to save a smaller proportion of the multipliers compared to classical Karatsuba using only square multipliers. However, since each rectangular multiplier is used almost to its full potential, the proposed technique saves resources and improves latency for large multipliers (above 64×64 bits). This is confirmed by actual synthesis results on recent Xilinx devices. Very large integer multipliers could be an important component for the booming field of fully homomorphic encryption (see for instance multipliers from 944×944 up to 2560×2560 bits in [7]).

II. CLASSICAL KARATSUBA METHOD

A. Two-Part Splitting

Consider a large multiplication of size 2W × 2W bits. It can be split into smaller multiplications of size W × W each by splitting the arguments into smaller segments of size W, leading to

\[ A \times B = (a_1 2^W + a_0)(b_1 2^W + b_0) \]

\[ = a_1 b_1 2^{2W} + (a_1 b_0 + a_0 b_1) 2^W + a_0 b_0 \]  

(1)

(2)

The basic idea of Karatsuba’s algorithm is based on the identity:

\[ a_1 b_0 + a_0 b_1 = (a_0 + a_1)(b_0 + b_1) - a_0 b_0 - a_1 b_1 \]

(3)

Hence, by reusing the sub-products M1 and M4, we can compute the sum of M2 and M3 by a single multiplication: this reduces the number of smaller multiplications from four to three. The price to pay are two new additions computing a_0 + a_1 and b_0 + b_1 (called pre-additions in the following),
and two additional negative terms in the final sum (called post- additions). Besides, the new product is a \((W+1) \times (W+1)\)-bit one, hence requires a slightly larger multiplier than each of the \(W \times W\)-bit products it replaces.

Karatsuba’s technique has been used in software for fast multiple-precision arithmetic. Equation (2) is applied recursively, and the recursion typically stops when the smaller multipliers match the capabilities of the hardware multipliers offered by the processor.

The present work addresses the design of large multipliers for FPGAs [3], [4], [8], [9]. It is closer to hardware multiplier design [10], [11]: the relevant metrics here are area and delay. Area-wise, Karatsuba reduces the cost for large enough values of \(W\). Exactly how large is technology-dependent, and we will only address here FPGA technology with embedded hard multipliers.

Delay-wise, post-additions may be performed in constant time using carry-save arithmetic. Equivalently, they can be merged with negligible overhead in the final bit array compression. Pre-additions, on the other hand, have a significant timing overhead due to the need for carry propagation. Therefore, Karatsuba will typically improve area, but degrade timing.

An alternative form of (2) is

\[
a_1b_0 + a_0b_1 = (a_1 - a_0)(b_1 - b_0) + M1 + M4. \tag{4}
\]

It uses pre-subtractions, which have the same hardware cost as pre-additions. However, the product is now a product of signed numbers. This will therefore be the preferred formulation on FPGAs, whose DSP blocks are capable of signed multiplication. The extra bit added by the pre-subtractions is now a sign bit, allowing us to exploit the sign bit inputs of each multiplier shown on Fig. 2(a), six of the 16 required \(W \times W\) bit multiplications can be saved. This corresponds to the number of tile pairs on the figure.

\[\text{Fig. 1: Graphical tiling representation of (2)}\]

B. Terminology and Graphical Representation

Throughout this article, we will use a tile-based graphical representation introduced in [4]. For instance, Fig. 1 illustrates the representation of (2). A multiplication is represented as a rectangle. Decomposing the inputs \(A\) and \(B\) into subwords splits this rectangle with vertical and horizontal lines respectively. Each of the sub-products appears as a smaller rectangle called a tile throughout this article. Fig. 1(a) shows square tiles, while Fig. 4 shows multiplications decomposed in rectangular tiles. When two multipliers are paired by Karatsuba, they are linked on the figure (Fig. 1(b)). Such a link means that the sum of the two linked tiles will be computed by a single multiplication, reusing the sub-products corresponding to tiles with black squares. The size of this multiplication is 1-bit larger than the tile size in both dimensions (and more if Karatsuba is applied recursively).

C. Square K-Part Splitting

The inputs to a large multiplication may also be split into \(K\) segments of \(W\) bits [12]:

\[
A \times B = \left( \sum_{i=0}^{K-1} 2^{iW} a_i \right) \left( \sum_{j=0}^{K-1} 2^{jW} b_j \right) \tag{5}
\]

\[
= \sum_{i,j} 2^{(i+j)W} a_i b_j \tag{6}
\]

In (6), any expression \(a_i b_j + a_j b_i\) may be replaced as follows:

\[
a_i b_j + a_j b_i = (a_i + a_j)(b_j + b_i) - a_j b_j - a_i b_i \tag{7}
\]

which again computes the sum of two tile subproducts using only one multiplier. The novelty is that subproducts may be reused more than one time, which further improves the efficiency of the method.

Take for example, a \(3W \times 3W\) multiplier where the arguments are split into three parts

\[
A \times B = (a_2 2^{2W} + a_1 2^W + a_0)(b_2 2^{2W} + b_1 2^W + b_0) \tag{8}
\]

\[
= a_0b_0 + (a_0b_1 + a_1b_0)2^W + (a_0b_2 + a_2b_0 + a_1b_1)2^{2W} + (a_1b_2 + a_2b_1)2^{3W} + a_2b_22^{4W} \tag{9}
\]

\[
= a_0b_0 + (a_0 + a_1)(b_0 + b_1) - a_0b_0 - a_1b_12^W + ((a_0 + a_2)(b_0 + b_2) - a_0b_0 - a_2b_2 + a_1b_1)2^{2W} + ((a_1 + a_2)(b_1 + b_2) - a_1b_1 - a_2b_2)2^{3W} + a_2b_22^{4W} \tag{10}
\]

Here, (7) could be used three times, which reduces the multiplier count from \(3 \times 3 = 9\) to only six.

The K-Part splitting is a straightforward application of rule (7) on as many partial products as possible. Figure 2 shows examples of 4-part, 6-part and 7-part splitting.

In general, K-Part splitting saves a triangle of \(K(K-1)/2\) multiplications. For instance, in the 4-part splitting of a \(4W \times 4W\) multiplier shown on Fig. 2(a), six of the 16 required \(W \times W\) bit multiplications can be saved. This corresponds to the number of tile pairs on the figure.

D. Recursive Karatsuba

The multiplication schemes above can also be applied recursively (it was actually the original formulation [1]), i.e., each multiplier is split into smaller multiplications where each of the smaller multiplication is itself split into smaller multiplications, etc.

Consider the \(4W \times 4W\) multiplication again. It can be realized by using three multiplications of up to \((2W + 1) \times (2W + 1)\) using the 2-part splitting in (2). Each of these \((2W + 1) \times (2W + 1)\) multiplications can then be realized by using three \((W + 1) \times (W + 1)\) multiplications by applying
another 2-part splitting. This leads to a total of only nine
\((W + 1) \times (W + 1)\) multiplications (compared to ten in the
4-part splitting). However, this comes at the price of additional
critical path delay or latency, as two pre-additions have to be
performed in sequence.

In other words, in hardware, the choice between \(K\)-part
splitting or its recursive application exposes a trade-off be-
tween latency and number of multipliers.

III. KARATSUBA WITH RECTANGULAR MULTIPLIERS

A. Generalized Square Karatsuba

Karatsuba works by pairing two multipliers \(a_i\) and \(a_j\),
which have the same weight \(2^w\) in the sum defining the large
multiplication. On a tiling representation such as Figure 2, this
means they are aligned on a NW-SE diagonal.

A first observation is that the pattern that results from
Karatsuba can be arbitrary shifted on the rectangle. In other
words it is possible to pair any tile that share the same weight:
as soon as \(i + j = k + \ell = s\), the complete product involves
\(2^w(a_i b_j + a_k b_\ell)\), and it is therefore possible to use the
rewriting

\[
a_i b_j + a_k b_\ell = (a_i + a_k)(b_j + b_\ell) - a_i b_\ell - a_k b_j
\]

or

\[
a_i b_j + a_k b_\ell = (a_i - a_k)(b_j - b_\ell) + a_i b_\ell + a_k b_j
\]

assuming \(a_i b_\ell\) and \(a_k b_j\) are already computed. Note that these
formulae generalize (7) and (4).

Graphically, this can be viewed as applying Karatsuba on
a sub-square of the large multiplier. This generalization is in
general less interesting than the classical \(K\)-part decompo-
sition, because the latter exposes more reuse of the diagonal
subproducts. However it could be used to apply Karatsuba
technique to non-square large multipliers: rectangular ones, or
truncated multipliers, for instance.

This generalization is also key to understanding how the
Karatsuba technique can reuse rectangular sub-products.

B. Weight-aligning Rectangular Tiles

In order to use (11) or (12) when the products are rectangu-
lar ones, they need to have the same binary weight. The trick
is therefore to find splittings of the two inputs that expose such
alignment.

Consider the splitting of argument \(A\) in \(W_A\)-bit chunks,
and argument \(B\) into \(W_B\)-bit ones. The weight of \(a_i b_j\) is now
\(2^{W_A+1+W_B}\). Therefore, for \(a_i b_j\) and \(a_k b_\ell\) to share the same
weight, we must have \(W_A i + W_B j = W_A k + W_B \ell\) for \(i \neq k\)
and \(j \neq \ell\). We can rewrite this as

\[
W_A N - W_B M = 0 \text{ with } N, M \in \mathbb{N}.
\]

Now, the smallest values of \(N\) and \(M\) to satisfy (13) are
obtained by \(M = W_A/W\) and \(N = W_B/W\) where \(W\) is
the greatest common divisor (GCD) of \(W_A\) and \(W_B\), i.e.,

\[
W = \gcd(W_A, W_B).
\]

Hence, the first common weight that appears is \(2^{W_A W_B}\). Thus,
the smallest multiplier for which Karatsuba can be applied is
of size \(W M(N + 1) \times W N(M + 1)\).

For example, consider a tile exactly matching the Xilinx
DSP block in unsigned mode: \(W_A = 17\) and \(W_B = 24\). As
\(W_A\) and \(W_B\) are relatively prime, we have \(W = 1, M = 17\)
and \(N = 24\). Relation (13) can only be satisfied for \(N\) being
multiples of 24 and \(M\) being multiples of 17, which is only
useful for very large multipliers starting from \(17 \times 24 = 408 \times 24\).

However, if we accept to use the slightly smaller tile size
\(16 \times 24\) (which means under-using the DSP blocks, but much
less than if we use them as \(17 \times 17\)), then we get a much
larger GCD \(W = \gcd(16, 24) = 8\), with \(M = 16/8 = 2\) and
\(N = 24/8 = 3\). The minimum large multiplier for which we
may apply Karatsuba is now \(8 \times 2 \times (3 + 1) \times 8 \times 3 \times (2 + 1) = 64 \times 72\).
This specific example is shown in Fig. 3(a). On this figure,
we made the choice that the index of each \(A\) chunks is \(2i\), and
the index of each \(B\) chunk is \(3j\), which makes it easier to spot
the situations where \(2i + 3j = 2k + 3\ell\).
Before we further look into specific implementation issues, we will first analyze different large multiplier sizes and their corresponding amount of small multipliers by using their polynomial representation.

IV. POLYNOMIAL INTERPRETATION

Fast multiplication algorithms are often described as polynomial multiplication [12], [13]. For instance (8) can be read as the product of two polynomials in the variable $x = 2^W$. The product of polynomials of similar orders corresponds to large multipliers that are approximately square. Let us consider a few potentially useful cases.

A large multiplier of size $W(N+1)M \times W(M+1)N$ corresponds to the following polynomial multiplication of an $N+1$-term $M$-sparse polynomial by an $M+1$-term $N$-sparse polynomial, both in $x = 2^W$:

$$\left( \sum_{j=0}^{N} a_{Mj}x^{Mj} \right) \left( \sum_{k=0}^{M} b_{Nk}x^{Nk} \right) = \sum_{i=0}^{2MN} c_i x^i. \quad (14)$$

For example, a large multiplier of size $8W \times 9W$, constructed from $2W \times 3W$ tiles, can be expressed as

$$(a_0 + a_2x^2 + a_4x^4 + a_6x^6) (b_0 + b_3x^3 + b_6x^6) = \sum_{i=0}^{12} c_i x^i. \quad (15)$$

The advantage of this representation is that we can identify the left-hand side and the right-hand side of (15), which provides the values of the polynomial coefficients:

$$
c_0 = a_0 b_0,
$$

$$
c_1 = 0,
$$

$$
c_2 = a_2 b_0,
$$

$$
c_3 = a_0 b_3,
$$

$$
c_4 = a_4 b_0,
$$

$$
c_5 = a_2 b_3,
$$

$$
c_6 = a_0 b_6 + a_6 b_0,
$$

$$
c_7 = a_4 b_3,
$$

$$
c_8 = a_2 b_6,
$$

$$
c_9 = a_6 b_3,
$$

$$
c_{10} = a_4 b_6,
$$

$$
c_{11} = 0,
$$

$$
c_{12} = a_6 b_6
$$

(16)

which shows where Karatsuba can be applied: one multiplier can be saved for $c_6$ on this example, with the Karatsuba identity $a_0 b_6 + a_6 b_0 = (a_0 - a_4) (b_0 - b_6) + c_0 + c_{12}$. This product requires eleven multipliers instead of twelve for the direct evaluation. The polynomial point of view also tells us that this is the optimal value, since there are eleven non-zero $c_i$ coefficients.

In general, such an algorithm can be derived that requires $MN + M + N$ multipliers, which is one less compared to the direct evaluation.

Another case is constructing a large multiplier of size $2WNM \times 2WMN$. Here, the polynomial multiplication can be written as

$$\left( \sum_{j=0}^{2N-1} a_{Mj}x^{Mj} \right) \left( \sum_{k=0}^{2M-1} b_{Nk}x^{Nk} \right) = (A_0(x) + A_1(x)x^{MN}) (B_0(x) + B_1(x)x^{MN}), \quad (17)$$

where

$$A_0(x) = \sum_{j=0}^{N-1} a_{Mj}x^{Mj},$$

$$A_1(x) = \sum_{j=N}^{2N-1} a_{Mj}x^{Mj-MN},$$

$$B_0(x) = \sum_{k=0}^{M-1} b_{Nk}x^{Nk},$$

$$B_1(x) = \sum_{k=M}^{2M-1} b_{Nk}x^{Nk-MN}.$$

(18)

Using a polynomial version of (2), (17) can be expressed using only three polynomial multiplications, each of which requires $MN$ multiplier tiles, so in total $3MN$ instead of $4MN$ multiplier tiles.

The last considered case is a large multiplier of size $W(2N+1)M \times W(2M+1)N$. This can be written similar to (17), but with

$$A_1(x) = \sum_{j=N}^{2N} a_{Mj}x^{Mj-MN},$$

$$B_1(x) = \sum_{k=M}^{2M} b_{Nk}x^{Nk-MN},$$

(19)

i.e., one more term in each of the $A_1(x)$ and $B_1(x)$ polynomials. Now, again, three polynomial multiplications can be computed based on (2). The multiplication $A_0(x)B_0(x)$ requires $MN$ multipliers as above. However, for $(A_0(x) + A_1(x)) (B_0(x) + B_1(x))$ and $A_1(x)B_1(x)$, it is now possible to use the approach for $W(N+1)M \times W(M+1)N$ multipliers leading to $MN + M + N$ multipliers. Besides, the product $a_{2MN}b_{2MN}$ appears in both polynomial multiplications, and, hence, only must be computed once. In total, a $W(2N+1)M \times W(2M+1)N$ multiplication require $3MN + 2M + 2N - 1$ rectangular multipliers instead of $4MN + 2M + 2N + 1$ for direct evaluation.

More complexity results for rectangular multipliers are summarized in Table I. The lower bounds are based on the number of non-zero coefficients in the resulting polynomial. It should be noted that the lower bounds can always be obtained, but sometimes the pre- and post-computation will become more complex. See, e.g., three-term multiplication with five square multipliers [14]. It requires division by three, but this operation is quite cheap on FPGAs [15]. This remains to be studied in detail.

V. DESIGN OF CONCRETE MULTIPLIERS

In the following, we consider the design of concrete multipliers targeting recent Xilinx FPGAs with DSP blocks providing a $18 \times 25$ signed multiplication.

A. Discussion on Other Possible Rectangular Tilings

A natural question to answer is: are there other possibilities of rectangular tilings like the $16 \times 24$ tiling discussed in Section III-B that would lend themselves to Karatsuba pairing?

We considered the following tiles:

- $18 \times 24$ (with one line of the multiplication performed using logic resources). This leads to $W = \text{gcd}(18, 24) = 6, M = 3$ and $N = 4$.
- $15 \times 25$ (under-using the DSP in one dimension, and again with one line of the multiplication performed using logic resources). This leads to $W = 5, M = 3$ and $N = 5$.

Figure 3 shows the smallest possible multipliers on which Karatsuba can be applied with these tiles. A detailed comparison of the resulting number of small multipliers when using one of the different options for $M$, $N$ and $W$ and the cases of Table I is given in Table II, sorted by the resulting large multiplier size. We conclude that Karatsuba opportunities are higher for the $16 \times 24$ configuration, and select this tile for actual evaluation in the rest of this work.

Besides, this configuration is also the simplest one to use as each tile uses just one DSP block without additional logic. As the result from the pre-addition grows in word size by one bit, it would require a $17 \times 25$ (unsigned) multiplication. However, it is simple to circumvent this by selecting the alternative form given in (12), which leads to subtractions in the pre-processing. The multiplier is now $17 \times 25$ signed, and this fits very well the $18 \times 25$ signed multiplier available in the DSP block.

B. Results on Concrete Multipliers

We designed several multipliers using the classical Karatsuba using square tiles, the conventional tiling (without any reduction) using rectangular tiles as well as the proposed Karatsuba method using rectangular tiles. The size of the square tiles was selected to be $17 \times 17$ and the rectangular tiles was selected to be $16 \times 24$ as discussed above. The sizes of the large multipliers were selected to be as close to each other as possible to achieve a direct comparison. The resulting tilings are shown in Fig. 4 and their concrete coefficients $c_t$ are given in appendix. Table III compares the operation counts in terms of their used amount of small multipliers, pre-adders and post-adders for all three methods.

The proposed Karatsuba method using rectangular tiles requires the least multipliers except in the $68 \times 68$ case, where classic Karatsuba uses one small multiplier less.

In terms of adders, the proposed method also significantly improves the numbers of pre- and post-adders. The main reason for this is of course the larger tile size, which leads to fewer sub-products, hence pre-adders.

Note that for the larger multipliers using the proposed method, many of the pre-adders can be shared as they compute the same values. For the $96 \times 96$, only 5 out of 12 pre-additions compute different values. For the $112 \times 120$ multipliers, only 7 pre-additions are required out of 16 (see appendix). For the traditional Karatsuba, no sharing is possible as each pre-addition only appears once.

VI. SYNTHESIS RESULTS

Table III shows the expected trade-off between multipliers and adders used for pre- and post-processing. To be able to compare the actual performance and resource consumption (including pipeline resources etc.), we designed a VHDL code generator for the multipliers using the different methods...
discussed above. It was integrated into the FloPoCo open-source code generator [16]. FloPoCo also provides a state-of-the-art framework to create and optimize compressor trees [17], [18]. It was used to implement all the post-adders within a single compressor tree. For each Karatsuba sub-product, one of the pre-adders was implemented using the pre-adder within the DSP block, while the other was implemented using logic. This further reduces about half of the pre-adders of Table III that are not shared.

Table IV shows synthesis results on Xilinx Virtex-6 using ISE. Results for Kintex-7 using Vivado are similar. As expected from Table III, the tiling approach typically requires the least logic resources in terms of look-up tables (LUTs) but the most DSP resources. Using the conventional Karatsuba with square multipliers helps reducing the DSP count but at the cost of a highly increased LUT count: more than 50% compared to the tiling approach. The proposed rectangular Karatsuba reduces the DSP count compared to the tiling approach with only a slight increase in logic resources. As a consequence, the latency (number of cycles) is also reduced.

VII. C ONCLUSION AND FUTURE WORK

In this work, an extension of Karatsuba’s method was presented that exploits rectangular-shaped multipliers. Necessary conditions were derived showing that Karatsuba’s method can be applied when the word lengths of the two inputs of these multipliers have a large GCD. Different large multipliers were designed for the general case, showing the benefits of the proposed extension compared to the conventional tiling. Based on that, several concrete multipliers were implemented for recent Xilinx FPGAs providing 18×25-bit signed multipliers in their DSP blocks. With this technique, a significant reduction in arithmetic operations (multipliers and adders) is possible. Synthesis experiments showed that this also predictively translates to a reduction of DSP blocks and logic resources.

The proposed technique is probably not useful when targeting ASIC or software, although it could find applications in the multiplication of polynomials with very specific sparseness properties.

Future work will be directed towards the further exploration

of possible large multiplier sizes, and exploring more formulæ [12]. Another goal is a fully automated design flow that selects the best fitting tile, integrated in a generic multiplier optimization framework [3], [9].
